

Short Communication

Is the Martinique ground snake *Erythrolamprus cursor* extinct?

STEPHANE CAUT and MICHAEL J. JOWERS

Abstract The Caribbean Islands are a biodiversity hotspot where anthropogenic disturbances have had a significant impact, causing population declines and extinction of endemic species. The ground snake *Erythrolamprus cursor* is a dipsadid endemic to Martinique; it is categorized as Critically Endangered on the IUCN Red List and is known only from museum specimens. The snake was common on Martinique during the 18th and 19th centuries but there have been no reliable sightings since 1968, suggesting it may have gone extinct, probably as a result of the introduction of the small Indian mongoose *Herpestes javanicus auro-punctatus*. However, the islet known as Diamond Rock, south-west of Martinique, is mongoose-free and the last reported sighting of *E. cursor* there was in 1968. The islet was last occupied during the Napoleonic Empire (the early 19th century), is now completely protected, and is difficult to access (it spans 5.8 ha, with a maximum elevation of 175 m). We conducted the first extensive survey of the islet, over 10 days, to clarify the status of *E. cursor*. Our study revealed that unique conditions exist on Diamond Rock (i.e. aridity and a distinct potential prey community) and that *E. cursor* would have had to modify its ecology to persist on the islet. Although the rugged terrain of Diamond Rock makes it difficult to explore, it is probable that *E. cursor* is now extinct.

Keywords Alien species, conservation, Diamond Rock, *Erythrolamprus cursor*, extinction, *Liophis cursor*, Martinique, West Indies

The Caribbean Islands are considered to be a biodiversity hotspot because they harbour a high concentration of endemic species that are threatened by habitat loss and invasive species (Myers et al., 2000). Of the region's herpetofauna, 99% of frogs and 93% of reptiles are endemic (Hedges, 2001). The Critically Endangered endemic dipsadid snake *Erythrolamprus cursor* (previously known as *Liophis cursor*, Lacépède, 1789, Plate 1) was common

throughout Martinique during the 18th and 19th centuries (Moreau de Jonnés, 1818). It was last observed on the Martinique mainland in 1965, when a single individual was caught near Fort-de-France. There are two potential reasons for its decline: people may have mistaken it for the venomous lancehead *Bothrops lanceolatus*, which may have led to its eradication, and the small Indian mongoose *Herpestes javanicus auro-punctatus*, an invasive predator, was introduced to the West Indies at the end of the 19th century, resulting in declines and extirpations of reptile species (Henderson, 1992).

To the south-west of Martinique, c. 2 km from the coast, lies a volcanic islet (spanning 5.8 ha, with a maximum elevation of 175 m; Fig. 1a; Plate 2) known as Diamond Rock. The last published record of *E. cursor* is associated with this unique ecosystem (the snake was observed there in 1962; Lazell, 1967), and the last specimen was collected on the islet in 1968 (Breuil, 2009). Diamond Rock was occupied by the English during the Napoleonic Wars (1804), when c. 100 men lived there for 17 months, sleeping in caves. Since this period of occupation few records of Diamond Rock have been kept but it seems to have remained uncolonized by the mongoose. The site is now fully protected and people have been banned from landing on the islet since 2008. Fishermen and tourist boats anchor near Diamond Rock, and there have been reports of snakes basking on shoreline rocks. However, several 1-day surveys for the species failed to locate it (Breuil, 2009; M. Dewynter, pers. comm.). The lack of any confirmed sightings of the snake since 1968 suggests that it is probably extinct (Honegger, 1981). The aim of this research was therefore to carry out an extensive survey to elucidate the species' status on Diamond Rock.

Because of the difficulty of exploring the steep slopes of Diamond Rock, and given its protected status, we surveyed the islet during 4–14 June 2014 as a two-person team. We used several methods to search for all potential traces of *E. cursor*. Firstly, eight snake-specific intercept traps (cylindrical cages 80 × 15 cm with cones at the extremities, modified after Linnell et al., 1998) were set in various microhabitats (near rocks, tree trunks, crevasses and at the base of stone walls; Fig. 1b) and were checked twice per day (80 trap-nights total; Table 1). Some traps were baited with live mice captured on the islet (8 trap-nights; Table 1). Secondly, we searched for snakes, snake eggs and sloughed skin in all the various habitats on the islet both during the day and

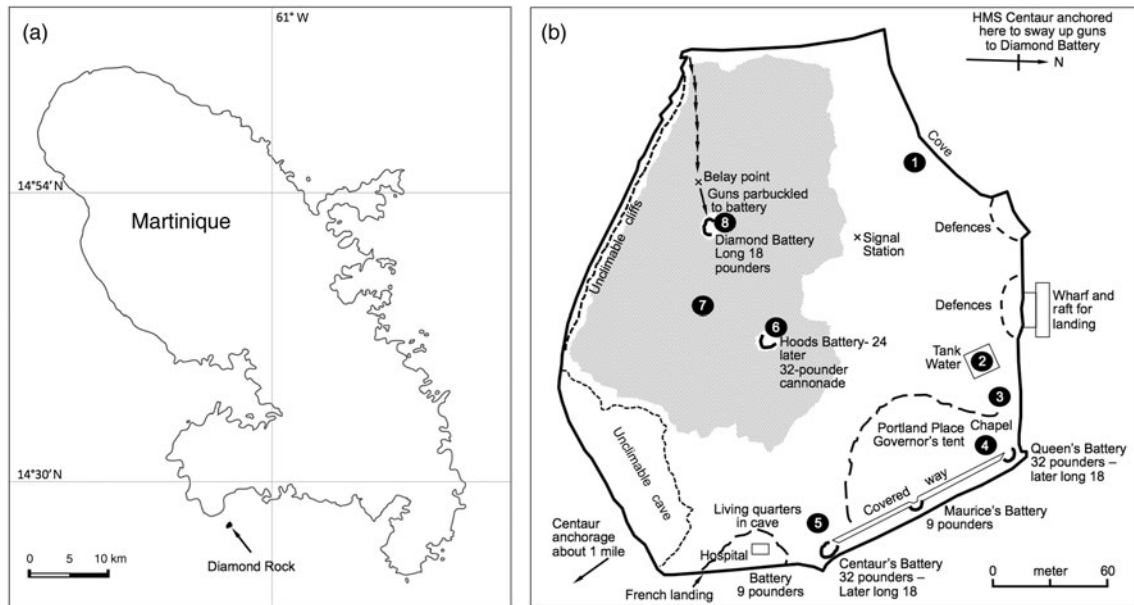

FIG. 1 (a) Location of Diamond Rock off the coast of Martinique; (b) map of Diamond Rock from the period of English settlement (Commodore Hood's dispatch, 14 August 1804; Stuart & Eggleston, 1978), with the locations of the eight trapping sites (filled black circles).

at night (12 hours per day per researcher). To examine *E. cursor*'s potential trophic relationships with other species on Diamond Rock (predator-prey and/or competitive interactions) we compiled an inventory of the species we observed during the survey. To confirm the presence of invasive rodents we used INRA rat traps (34 × 13 × 13 cm) and mouse traps (12 × 5 × 5 cm) baited with peanut butter. Trap lines were established in various habitats (six sites; Fig. 1b), 25 and 5 m apart for rats and mice, respectively. For logistical reasons we could only use 14 traps (six rat traps and eight mouse traps), which we moved between sites. Trapping was conducted for 1 or 2 consecutive nights on each line transect (a total of 119 trap-nights; Table 1).

We did not detect any signs of the snake. The intercept traps functioned well because we captured all the reptile species that we observed during our visual surveys (Table 1). Although some remote areas of the islet remain unexplored for logistical reasons, our survey covered more of Diamond Rock's surface than previous surveys. We ascended steep slopes, whereas previous researchers focused on accessible rocks at low elevations (Lazell, 1967), surveyed for only a few hours, and did not explore the islet extensively. In reports written during the English occupation of Diamond Rock (Stuart & Eggleston, 1978) snakes were described as abundant near the edge of the water tank (site 2, Fig. 1). The last time *E. cursor* was observed on Diamond Rock was in July

TABLE 1 The number of trap-nights with rodent traps (for rat and mice traps, see text for details, combined) and with interception traps for snakes (with number of nights on which traps were baited with live mice), with the species caught in each, at the eight survey sites (see numbered locations on Fig. 1) on Diamond Rock (Fig. 1).

Site	Rodent traps		Interception traps	
	No. of trap-nights	Species trapped	No. of trap-nights (no. of trap-nights with live mice bait)	Species trapped

1962 (Lazell, 1967). Weather and temperature conditions during our survey in June (including some precipitation) should have been favourable to observing the snake. Some seabirds (e.g. bridled tern *Onychoprion anaethetus*, red-billed tropicbird *Phaethon aethereus*, brown noddy *Anous stolidus*) breed on Diamond Rock during this season, which could have enhanced the likelihood of spotting the snake if it had adapted to consume eggs or juvenile birds.

Proving the absence of a species is notoriously difficult, and previous work on *Erythrolamprus ornatus* on Maria Major Island, Saint Lucia, suggests that snakes are difficult to survey, with as few as one located per 30 days of searching (J. Daltry, pers. comm.). Although, it seems likely that *E. cursor* is extinct, what allowed the species to be abundant on Diamond Rock in the 18th century and persist until the 1950s? Given the aridity on the islet and its distinct prey communities *E. cursor* would have had to modify its ecology to persist on the islet. Although the genus *Erythrolamprus* contains 48 species little is known about their ecology and diet, and living *E. cursor* have never been studied. Studies of the species' trophic ecology (Henderson & Bourgeois, 1993; Henderson, 2004) were based on the stomach contents of preserved specimens, indicating consumption of frogs (*Eleutherodactylus* spp.) and lizards (*Anolis* spp.) and a small proportion of insects. The closest living related species, *Erythrolamprus juliae* (Jowers et al., 2013), has a similar diet, comprising mainly anurans (Schwartz & Henderson, 1991; Breuil, 2002). There have not been any reports of frogs on Diamond Rock and we found no evidence of them, and therefore *E. cursor* probably underwent a dietary shift to prey on the species available (e.g. four reptile species; Table 1). We found that the Martinique anole *Anolis roquet* was common, especially at lower elevations. Other potential prey present at high densities included seabird chicks, juvenile Antillean fruit-eating bats *Brachyphylla cavernarum*, and invasive house mice *Mus musculus*.

Another cause of the snake's disappearance could be the introduction of non-native predators. Diamond Rock was granted full protection only in 2008. During our survey we found no evidence of the presence of superpredators on the islet (e.g. mongoose or feral domestic cat). We did not capture any rats *Rattus* spp., and based on our experience trapping rodents on other oceanic islands we are confident there are no rats on Diamond Rock and probably never have been. However, mice appear to be present at high densities. They can have devastating, irreversible and ecosystem-changing effects on islands and are known to consume invertebrates, seabird eggs and juvenile seabirds (Angel et al., 2009). On Diamond Rock mice could have affected the snake population directly by consuming juvenile snakes or snake eggs, or indirectly by decreasing prey availability. Egg clutches of *E. cursor* may have contained no more than five eggs (Arlington & Henderson, 2004). However, as the mouse population dates from the time of the English occupation in 1804, why was the snake still present on the islet <50 years ago?

Lack of data on the species' abundance in the 1950s is a significant limitation to evaluating the cause of the species' extinction. There may never have been a large population of *E. cursor* on Diamond Rock, or the population may have decreased during the English occupation. If *E. cursor* on Diamond Rock lived at the same density as *E. ornatus* on Maria Major (1.7–8.3 individuals per ha; J. Daltry, pers. comm.), this would imply <50 individuals in total. Such a low-density population would probably suffer from inbreeding depression (e.g. reduced fertility, congenital defects, reduced resistance to disease) and be vulnerable to stochastic forces such as a skewed sex ratio, natural disasters and chance fluctuations in reproduction and mortality (Traill et al., 2007). Alternatively, the disappearance of *E. cursor* may have resulted from a particular event (e.g. climatic change, species invasion)

that took place between the 1950s and 2008, when the islet became fully protected.

Although the complexity of the Diamond Rock ecosystem makes it difficult to explore, we conclude that *E. cursor* may now be extinct, given that 10 days of extensive surveying and trapping yielded no signs of its presence. It is more difficult to declare a species extinct than to describe or rediscover species. *Erythrolamprus cursor* is just one example of several reptile species known to survive only on one small island, at a low density (e.g. *E. ornatus*, *Alsophis antiguae*, *Cnemidophorus vanzoi*, *Ameiva polops*). There is an urgent need to assess these species and to ensure that their habitats are free from invasive species and other potential threats. The invasion of oceanic islands by non-native predators can lead to dramatic effects on island ecosystems and cause numerous extinctions. From a conservation perspective, the Caribbean, a biodiversity hotspot with a large number of species at risk of extinction, is one of the most important areas in the Western Hemisphere.

Acknowledgements

We thank L. Juhel, I. Ineich and M. Breuil for their help in organizing the survey, and A. Bérubé-Lampron for the documentary films. We also thank Jessica Pearce-Duvet for her English editing services. Appropriate ethical procedures were employed during this research. SC was granted approval to engage in animal experimentation (R-45GRETA-F1-04) by the French Minister of Agriculture. DEAL Martinique (J. Mailles, N. Boulard and C. Barnérias), the Conservatoire du Littoral, and ONCFS provided legal support (DEAL-20130510) and allowed us access to Diamond Rock and its facilities. This work was funded by the Consejo Superior de Investigaciones Científicas (JAE postdoctoral contract to SC) and the NGO Animal Conservation.

Biographical sketches

STEPHANE CAUT studies the ecology and conservation of threatened species. Much of his work focuses on ecosystem functioning and the key role played by vertebrate species and/or invasive species. Using a multidisciplinary approach (field, laboratory, modelling, and experimental), he seeks to understand biological and trophic interactions among species. He specializes in isotopes, using them to address species- and ecosystem-level conservation challenges across a wide range of taxa and habitats. MICHAEL JOWERS studies evolutionary biology, applying population genetics, phylogeography, and biogeography. He uses the phylogenetic species concept to assess the taxonomy of poorly described reptiles and amphibians. Most of his work has focused on reptiles and amphibians native to the islands of Trinidad and Tobago but he has also worked on other organisms, including mammals, social insects, scorpions, freshwater fish and parasites.
